Abstract

Objective. Blood flow is one such available observable promoting a wealth of physiological insight both individually and in combination with other metrics.

Approach. Near-infrared diffuse correlation spectroscopy (DCS) and, to a lesser extent, diffuse correlation tomography (DCT), have increasingly received interest over the past decade as noninvasive methods for tissue blood flow measurements and imaging. DCS/DCT offers several attractive features for tissue blood flow measurements/imaging such as noninvasiveness, portability, high temporal resolution, and relatively large penetration depth (up to several centimeters).

Main results. This review first introduces the basic principle and instrumentation of DCS/DCT, followed by presenting clinical application examples of DCS/DCT for the diagnosis and therapeutic monitoring of diseases in a variety of organs/tissues including brain, skeletal muscle, and tumor.

Significance. Clinical study results demonstrate technical versatility of DCS/DCT in providing important information for disease diagnosis and intervention monitoring.

Keywords: diffuse correlation spectroscopy and tomography, microvascular blood flow, diagnosis, therapeutic monitoring, clinical application

1. Introduction

Near-infrared (NIR) diffuse optical technologies have gained popularity in recent years as simple, fast, continuous, portable, and relatively inexpensive methods for noninvasive quantification of hemodynamics and metabolism in deep tissues up to several centimeters (Jobsis 1977, Boas et al 2001, Bouye et al 2005, Schachner et al 2008, Vardi and Nini 2008, Murkin and Arango 2009, Shuler et al 2009, Ferrari et al 2011). One type of NIR technology, namely near-infrared spectroscopy (NIRS) or diffuse optical spectroscopy (DOS), takes advantage of the low absorption spectrum of biological tissues in the NIR range (650–950 nm) and penetrates deep tissues to detect light absorption by oxy-hemoglobin (HbO2) and deoxy-hemoglobin (Hb) in red blood cells (RBCs) (Strangman et al 2003, Kim et al 2005). As a result, oxy-, deoxy-, total- hemoglobin concentrations (i.e. [HbO2], [Hb], and THC) and tissue blood oxygen saturation (StO2) in local tissue microvasculature can be quantified (Fantini et al 1995, Liu et al 1995, Boas et al 2001, Wolf et al 2003). Over past decades, a variety of NIRS/DOS technologies have been extensively explored to study various diseases affecting blood oxygenation levels in local and regional tissues (Patterson et al 1989, Fantini et al 1995, Liu et al 1995, Wolf et al 2003, Quaresima et al 2004, Al-Rawi and Kirkpatrick 2006). Correspondingly, diffuse optical tomography (DOT) based on NIRS/DOS has also been developed for 3-dimensional (3D) imaging of oxygenation distributions in organs or regional tissues (Arridge and Hebden 1997, Dehghani et al 2010, Jermyn et al 2013, Zhang et al 2013, Eggebrecht et al 2014).

Another emerging NIR technology, diffuse correlation spectroscopy (DCS), has also been developed to directly measure blood flow variations in deep tissue microvasculature (Pine et al 1988, Maret and Wolf 1989, Boas et al 1995, Boas 1996, Durduran 2004, Choe 2005, Yu et al 2005a, Jiaillon et al 2007, Zhou 2007, Irwin 2011, Gurley 2012, Cheng 2013, Dong 2015, He 2015). DCS uses coherent NIR light to penetrate deep tissues and monitors temporal light intensity fluctuation caused by moving scatterers (primarily RBCs in the microvasculature) to extract a blood flow index (BFI) (Cheung et al 2001, Irwin et al 2011). The relative change of blood flow (rBF) is calculated by normalizing BFI to its baseline value before the physiological change occurs. DCS measurements of tissue blood flow changes have been extensively validated against other standards, including power spectral Doppler ultrasound (Yu et al 2005b), Doppler ultrasound (Buckley et al 2009, Roche-Labarbe et al 2010), laser Doppler (Durduran 2004, Shang et al 2011a), Xenon computed tomography (Xenon-CT) (Kim et al 2010), fluorescent microsphere flow measurement (Zhou et al 2009), and arterial spin labeling magnetic resonance imaging (ASL-MRI) (Yu et al 2007). In some studies, DCS has been combined with NIRS/DOS in hybrid instruments to simultaneously measure tissue blood flow and oxygenation (Durduran et al 2004, Yu et al 2005a, Cheng et al 2012, Gurley et al 2012, Munk et al 2012, Shang et al 2012), which allows for the derivation of metabolic rate of tissue oxygen consumption.

Despite advances in DCS applicability, there have been limited tomographic imaging realizations. An early contact-measurement based 3D diffuse correlation tomography (DCT) approach using an optical fiber array was applied to tissue phantoms with a semi-infinite geometry (Boas and Yodh 1997), but is disadvantaged in vivo due to the irregular geometries of biological tissues. A few noncontact-measurement based DCT examinations have been recently conducted to avoid tissue hemodynamic variations induced by the probe compression or the disturbance of sensitive tissue areas (Culver et al 2003, Zhou et al 2006, Lin et al 2014, He et al 2015, Huang et al 2015a, 2015b). In these noncontact measurement systems, lenses were positioned between a sample and an optical fiber array connected to the light sources and detection elements. The noncontact DCS/DCT has been successfully applied in examining...

Since NIRS/DOS/DOT technologies for tissue blood oxygenation measurements have been broadly reviewed (Wolf et al. 2007, Durduran et al. 2010a, Ferrari et al. 2011, Ghosh et al. 2012), our review focuses on the DCS/DCT technologies for tissue blood flow measurements in the clinic. We first introduce the principle and instrumentation of DCS/DCT. We then provide typical clinical examples of DCS/DCT for the diagnosis of diseases and therapeutic monitoring of interventions in a variety of organs/tissues such as brain, skeletal muscle, and tumor. Finally, we highlight the limitations of DCS/DCT and point out future perspectives in technology development and clinical applications.

2. DCS/DCT methods

2.1. Diffuse correlation spectroscopy (DCS)

DCS originates from the concept of ‘dynamic light scattering (DLS)’, a technology that can be used to quantify the motion of moving scatterers in a thin solution through investigating the correlation of light electric field after photons are scattered once by the moving scatterers (i.e. single light scattering) (Fletcher 1976, Brown 1993). The extension from single light scattering to multiple light scattering has been explored since 1980s (Maret and Wolf 1987, Pine et al. 1988, Boas et al. 1995). This extension, called diffusing-wave spectroscopy (DWS) (Pine et al. 1988, Li et al. 2005, Jaillon et al., 2006) or diffuse correlation spectroscopy (DCS) (Boas et al. 1995, Boas and Yodh 1997, Cheung et al. 2001, Yu et al. 2005a, Gagnon et al. 2008), makes it possible to quantify the motion of moving scatterers in a thick sample, such as red blood cells (RBCs) flowing through biological tissues.

The principle and instrumentation of DCS have been described elsewhere (Boas et al. 1995, Cheung et al. 2001, Irwin et al. 2011, Durduran and Yodh 2014, Yu 2012a, 2012b, 2012c). Briefly, a long-coherence laser delivers NIR light via an optical fiber to the tissue (figure 1(a)). Photons entering into the tissue are either absorbed or more dominantly, scattered by static scatterers (e.g. organelles and mitochondria) and dynamic scatterers (mainly moving RBCs). Due to the scattering effect photons may change directions many times while traveling throughout the tissue, resulting in light diffusion. Only a few photons can eventually reach tissue surface and be collected by a single-mode detector fiber placed millimeters or centimeters away from the source fiber. Photons collected by the detector fiber are detected by a single photon-counting avalanche photodiode (APD) to yield light intensity signals (figure 1(b)).

The detected light intensity fluctuates with time (figure 1(b)), which is caused by the motion of moving scatterers (mainly RBCs) inside the tissue volume measured. To quantify the motion of RBCs (i.e. blood flow) the normalized light intensity temporal autocorrelation function ($g_2(\tau)$) is calculated by a hardware correlator board or a software correlator, which can then be converted to the normalized electric field temporal autocorrelation function ($g_1(\tau)$, figure 1(c)) through the Siegert relation (Rice 1954):

$$g_2(\vec{r}, \tau) = 1 + \beta |g_1(\vec{r}, \tau)|^2$$

where $\tau$ is the correlation delay time, $\vec{r}$ is the position vector, and $\beta$ is a parameter which is dependent of laser stability, coherence length, and the number of speckles detected.

The $g_1(\tau)$ can be expressed in an integral form (Maret and Wolf 1987, Pine et al. 1988, Boas and Yodh 1997, Li et al. 2013)
Here $E(0)$ and $E^*(\tau)$ are the scattered light electric field at time 0 and its conjugation at time $\tau$, respectively. $P(s)$ is the normalized distribution of detected photon path length $s$, $k_0$ is the wave vector magnitude of the light in the medium, and $l^*$ is the photon random-walk step length, which is equal to $1/\mu_s$ ($\mu_s$ is the medium reduced scattering coefficient).

\begin{equation}
    g_s(\tau) = \frac{\langle E(0)E^*(\tau) \rangle}{\langle |E(0)|^2 \rangle} = \int_0^\infty P(s) \exp\left(-\frac{1}{3} k_0^2 \langle \Delta r^2(\tau) \rangle \frac{s}{l^*} \right) ds
\end{equation}

**Figure 1.** The principle of diffuse correlation spectroscopy (DCS) for blood flow measurements in deep/thick tissues. (a) Source and detector fibers are placed on the tissue surface within a distance of $r$ for light delivery and collection; (b) light intensity $I(t)$, detected by the APD, fluctuates with time due to the motions of RBCs; (c) blood flow change can be quantified from the shift of temporal electric field autocorrelation function curves.
The unknown $\langle \Delta r^2(\tau) \rangle$ represents the mean-square-displacement of moving scatterers, which is conventionally difficult to be solved directly using equation (2). Alternately, the integral form of autocorrelation function can be converted to a partial differential equation form (Pine et al. 1990). As such, the unnormalized electric field autocorrelation function $G_\tau(\tau) = \langle E(0)E^*(\tau) \rangle$ satisfies a correlation diffusion equation (Boas and Yodh 1997, Cheung et al. 2001)

$$\left( D \nabla^2 - \nu \mu_s - \frac{1}{3} \nu \mu_s' k_0^2 \langle \Delta r^2(\tau) \rangle \right) G_\tau(\bar{r}, \tau) = -\nu S(\bar{r}) \quad (3)$$

Here, $\nu$ is the light speed in the medium; $\mu_s$ is the medium absorption coefficient; $D \approx \nu / \beta \mu_s'$ is the medium photon diffusion coefficient, and $S(\bar{r})$ is the continuous-wave isotropic source. The form of $\langle \Delta r^2(\tau) \rangle$ depends on a flow model specifically adopted. For example, a diffuse model, i.e. $\langle \Delta r^2(\tau) \rangle = 6D_B \tau$, has been found to fit experimental data well over a wide range of different tissues (Cheung et al. 2001, Irwin et al. 2011). Here, $D_B$ is the effective diffusive coefficient. To account for the fact that not all scatterers are ‘moving’ in the tissue, a factor $\alpha$, representing the ratio of ‘moving’ scatterers to the total number of scatterers, is added to $\langle \Delta r^2(\tau) \rangle$ (i.e. $\langle \Delta r^2(\tau) \rangle = 6\alpha D_B \tau$). The combined term, $\alpha D_B$, is referred to as blood flow index (BFI) in biological tissues. The $\alpha D_B$ can be extracted by fitting the measured autocorrelation function curve to an analytical solution of the correlation diffusion equation (equation (3)) under certain geometries (e.g. semi-infinite boundary) (Cheung et al. 2001, Roche-Labarbe et al. 2010, Irwin et al. 2011, Dong et al. 2012a).

2.2. Diffuse correlation tomography (DCT)

The extension of DCS to DCT is comparable to that of DOS extension to DOT, which images the optical property distribution based on photon diffusion equation and its inverse solutions (i.e. image reconstruction). A DOT instrument typically illuminates tissue and measures the diffusive light leaving the tissue with multiple sources and detectors on the tissue boundary (Dehghani et al. 2009, Intes et al. 2010, Zhang et al. 2013, Eggebrecht et al. 2014). The diffusive propagation of light in tissue can be characterized with photon diffuse equation and parameterized in terms of the unknown $\mu_s(\bar{r})$ and $\mu_s'(\bar{r})$ at different locations $\bar{r}$ of the measured tissue volume. One can then ‘invert’ the propagation model to recover these unknown parameters.

Similarly, DCT requires a large number of sources and detectors to measure autocorrelation functions on the tissue boundary. Early DCT approaches rely on analytical solutions of equation (3) with the assumption of simple semi-infinite geometries and/or strict heterogeneities (e.g. spherical anomaly) of tissues (Culver et al. 2003, Zhou et al. 2006), which precludes the transition to complex boundaries and imperfect heterogeneities in realistic tissues.

The finite-element-method (FEM) framework has been applied to model light transport in highly diffuse media to resolve the geometry and heterogeneity limitations for DOS/DOT (Arridge and Hebden 1997, Arridge and Lionheart 1998, Dehghani et al. 2009, Jermyn et al. 2013, Eggebrecht et al. 2014). For example, NIRFAST (www.nirfast.org) (Dehghani et al. 2009, Jermyn et al. 2013) and TOAST ++ (http://web4.cs.ucl.ac.uk/research/vis/toast/) (Schweiger and Arridge 2014) are publically available image reconstruction toolboxes based on the diffusive model and FEM for DOT.
Exploiting the high mathematical similarity of the forward and inverse problems (e.g. boundary conditions and mathematical assumptions) between DOT and DCT, our group first reported the application of FEM in DCT (Lin et al. 2014, He et al. 2015, Huang et al. 2015a, 2015b). We introduced this concept into the FEM-based light transport and image reconstruction modules in NIRFAST (Dehghani et al. 2009), as a shortcut for FEM implementation of DCT. Specifically, we used the ‘effective’ $\mu_s(\vec{r})$ (i.e. $\mu_s(\vec{r}) + 2\mu_s'(\vec{r})k_0^2\Delta\alpha D_0(\vec{r})\tau$) and measured $G(\vec{r},\tau)$ to replace the $\mu_s(\vec{r})$ and photon fluence rate $\Phi(\vec{r}, t)$ respectively in the NIRFAST for the accomplishment of DCT in tissues with complex boundaries (Lin et al. 2014, He et al. 2015, Huang et al. 2015a, 2015b). Computer simulations, phantom tests, and in vivo studies have verified the accuracy of our modifications of NIRFAST adapted for DCT. As a result, the realm of DCT becomes available for comprehensive imaging under complex geometries and heterogeneous optical properties.

2.3. DCS/DCT instrumentation

Typical DCS/DCT systems are illustrated in figure 2. The DCS/DCT systems consist of long-coherence NIR lasers (e.g. 785 nm, Crystalaser, USA), single photon-counting APDs (e.g. SPCM-AQR-12, Perkin Elmer Inc., Canada), and digital correlator boards (e.g. FLEX03LQ, www.correlator.com, USA). A control panel (laptop or desktop) is used to control the DCS/DCT system for data collection and calculation of temporal autocorrelation function via the correlator board. Blood flow index ($\alpha D_B$) can be extracted by fitting the measured autocorrelation function curve to an analytical solution of equation (3) under certain geometries. In contrast to the portable DCS device (b) with a limited number of sources and detectors, the DCT instrument (c) has a large number of sources and detectors for 3D flow imaging.

A variety of fiber-optics probes have been designed for DCS (figure 3) and DCT (figure 4) measurements in different applications (Durduran et al. 2005, Yu et al. 2011, Shang et al. 2011b, Huang et al. 2015b, 2015c) (see section 3). These probes are connected to the DCS/DCT instruments (figure 2) through optical fibers for light delivery and detection. Examples of DCS probes for the studies of brains, skeletal muscles, and tumors are illustrated in figures 3(a)–(e), respectively. For instance, a hand-held probe was designed to scan over a breast tumor in both horizontal and vertical directions for diagnostic purpose (Durduran et al. 2005) (figure 3(d)). For the tissues whose shapes promote hemodynamic variations induced by compression or disturb sensitive areas, DCS probes were designed in a noncontact manner (Huang et al. 2015c) (figure 3(f)). In the noncontact measurement design, a lens system with separated source and detector paths was utilized to focus the light from the source and detector fibers on the measured tissue surface. The noncontact DCS (ncDCS) probe was also extended to a noncontact imaging probe head for DCT measurements, which consisted of a linear array of 15 photodetectors and two laser sources connected to a mobile lens-focusing system (figure 4) (Lin et al. 2014, He et al. 2015, Huang et al. 2015b). A motorized stage was utilized for automatic scanning (figure 4(a)), enabling large ROI coverage and flexible S-D arrangements without greatly increasing hardware requirements and costs (figure 4(b) and figure 4(c)). This new design of noncontact DCT (ncDCT) probe, combined with a novel FEM framework for DCT image reconstruction, has been validated in a tissue-like phantom with anomaly flow contrast design (Lin et al. 2014) and has been applied in detection of breast tumors (He et al. 2015, Huang et al. 2015b). In practice, any innovations adopted in DOS/DOT probes can be adapted for the design of DCS/DCT probes, and a combined probe integrating DOS/DOT and DCS/DCT measurements can be constructed by adding extra optical fibers.
3. Clinical application examples

3.1. Brain

3.1.1. Diagnosis of cardio-cerebral diseases. DCS has been explored for the diagnosis and evaluation of cardio-cerebral diseases affecting cerebral blood flow (CBF) in adults, children, and neonates. For example, DCS was utilized to investigate CBF responses in adult patients with cerebral diseases including vasovagal syncope (Cheng et al 2014), obstructive sleep
Figure 3. A variety of optical probes for DCS/DCT measurements. (a) A typical DCS probe consisting of source and detector fibers; (b) two DCS probes taped on both sides of a frontal head for cerebral blood flow measurements; (c) a DCS probe taped on top of the calf muscle; (d) a hand-held DCS probe scanning over a breast tumor; (e) a DCS probe placed on top of the head/neck tumor; (f) a noncontact DCS probe with lens system focusing the source and detectors on the surface of tissue. Some of the figures are reproduced from the subfigures in Durduran et al (2005) and Huang et al (2015c)

Vasovagal syncope (VVS) is the sudden loss of consciousness, which can be fatal if occurring in public such as driving and flying. In a study of CBF variations to predict VVS (Cheng et al. 2014), a 70° head-up-titling (HUT) protocol was applied to 14 healthy adults, and relative changes of CBF (rCBF) to the baseline were continuously monitored using a fiber-optic probe illustrated in figure 3(a). In addition, relative changes of main artery blood pressure (rMAP) were also continuously monitored using a noninvasive finger sensor (Portapres, FMS Inc., Netherlands). In the subjects having presyncope symptoms during HUT, physiological responses to the tilting were observed to have two stages; while Stage I showed a small changes, Stage II demonstrated a rapid and dramatic decreases in both rCBF and rMAP that were coincided with presyncope symptoms (figure 5). On average, rCBF reached the Stage II earlier and decreased larger (76 ± 8%, from a baseline of 100%) than rMAP (39 ± 19%, assigning a baseline value of 100%) during presyncope. Moreover, a threshold of ~50% rCBF decline was determined to completely separate the subjects with or without presyncope. This

Figure 4. A noncontact DCT probe with rotational scanning system. (a) Noncontact DCT probe head was scanned over a region of interest (ROI) on the breast by a motorized rotational stage, (b) a linear array of single-mode detector fibers, (c) source and detector fibers were projected on the breast surface using achromatic lenses; two source paths were attached to the sides of the detector path. This figure is reproduced from figure 1 in Huang et al. (2015b).
study suggests that continuous monitoring of CBF variations by the portable DCS device may provide predictive information to prevent VVS (e.g. using an automatic feedback to maintain MAP and CBF at normal levels).

Another example of DCS applications is the study of obstructive sleep apnea-hypopnea (OSAH) (Hou et al. 2014), a disease characterized by repetitive pausing of breath resulted from upper airway obstruction during sleep. The impeded airflow during OSAH may cause cerebral ischemia and disturb CBF. Although OSAH can be diagnosed through monitoring of overnight sleep with a polysomnography, evaluation of cerebral ischemia and hypoxia induced by OSAH is not routinely conducted, due to lack of appropriately technologies. Using a dual-wavelength DCS flow-oximeter (Shang et al. 2009), our group conducted continuous and simultaneous measurements of relative changes of CBF, oxy- and deoxy- and total hemoglobin concentrations ($\Delta$Cbf, $\Delta$[HbO2], $\Delta$[Hb], $\Delta$THC) in adult subjects with OSAH for ~8 h overnight (Hou et al. 2014). Two fiber-optic probes connected to the DCS flow-oximeter were taped on both sides of the subject’s forehead for cerebral monitoring during sleep (illustrated in figure 3(b)). To minimize the disturbance to patients, we remotely operated the optical measurements in a control room and designed special fiber-optic connectors which could easily disconnect the probes when the patient went to bathroom. The results showed that apneic events caused significant variations in rCBF and $\Delta$THC. Moreover, the degrees of these hemodynamic variations were significantly correlated with the severity of OSAH.

Similarly, DCS was also adopted to measure CBF responses to hypercapnia during wakefulness rather than during sleep in children with obstructive sleep syndrome (OSA) and/or snores (Busch et al. 2016a). Both OSA and snore subjects were found to have significant less changes in CBF during hypercapnia than health controls, indicating the diseased-induced blunted brain responses.

DCS was also utilized to monitor CBF variations in adults with traumatic brain injury (Kim et al. 2010, 2014) or ischemic stroke (Durduran et al. 2009, Favilla et al. 2014). In those studies, CBF changes were found to be associated with large variations in cerebral blood pressure.

Figure 5. Relative changes in mean artery blood pressure (rMAP) and cerebral blood flow (rCBF) from a control subject (a) and a presyncope subject (b) during head-up-tilting (HUT). The solid vertical lines indicate the beginning or ending of tilting up and tilting down. The triangles indicate the minima of rMAP and rCBF during HUT. The two connected dashed lines on top of the raw data (b) demonstrate the two-line fitting results. The dashed vertical lines indicate the break-points separating stage I and stage II. This figure is reproduced from the subfigures of figure 1 in Cheng et al (2014).
induced by physiological manipulations (Durduran et al 2009, Kim et al 2010, Favilla et al 2014), indicating the impairments of cerebral autoregulation to maintain a constant CBF.

In addition to the applications in adults and children, DCS was employed to assess CBF in neonates with malfunctions/defects and during surgical treatments, including those with congenital heart disease (CHD) (Durduran et al 2010b), hypoxic ischemic encephalopathy (Dehaes et al 2014), single-ventricle CHD undergoing surgery (Dehaes et al 2015), as well as the neonates during open heart surgery (Busch et al 2016b). In those studies, DCS measurements benefited from higher signal-to-noise ratio (SNR) due to the thinner skulls of neonates.

When subjected to a protocol of CO₂ inhalation for inducing hypercapnia (Durduran et al 2010b), CBF values in neonates with CHD were elevated significantly (158 ± 6%, assigning a baseline of 100%), which were detectable by both DCS and ASL-MRI measurements. Since complex CHD may lead to impaired cerebral autoregulation and low-baseline CBF, this study explored the potential of DCS for longitudinally probing cerebral defects in critically ill neonates.

Apart from physiological challenging mentioned above, CBF values before and after heart surgeries were measured and compared between the neonates with single-ventricle CHD and healthy controls (Dehaes et al 2015). The results showed impaired cerebral development in diseased neonates, as characterized by decreased CBF. Furthermore, CBF was continuously monitored during neonatal open heart surgery, an intervention aiming to treat heart defects (Busch et al 2016b). Significant variations in CBF during deep hypothermia, circulatory arrest, and rewarming were observed, indicating the capability of DCS for cerebral hemodynamic monitoring in a highly challenging clinical environment.

In study of cerebral hemodynamics in premature neonates (Roche-Labarbe et al 2010), a steady increase (28%, from a baseline of 100%) in CBF was found over the first six weeks of life, indicating that the neonates gained improvements in brain microcirculation since birth. In another study of extremely preterm neonates, the subjects with hemorrhage were found to have lower CBF when compared with those without hemorrhage (Lin et al 2016). Similarly, lower CBF levels in neonates with hypoxic ischemic encephalopathy were reported, compared to age-matched healthy neonates (Dehaes et al 2014).

In summary, many cardio-cerebral diseases affect nervous system, cerebral microvasculature, and cerebral oxygen kinetics, leading to abnormality in CBF (Mesquita et al 2011, Durduran and Yodh 2014). Therefore, CBF is considered as an important biomarker of brain health, which links the oxygen demand, supply, and consumption. Continuous measurements of CBF in the clinical setting, however, are not easily achievable due to technology unavailability. DCS offers a continuous, fast, portable, and low-cost tool to noninvasively monitor CBF variations at the bedside of the clinic. Studies presented in this subsection demonstrate that CBF abnormalities are associated with a variety of cerebral diseases. While the explicit relationships between CBF abnormalities and clinical outcomes need to be further investigated, these studies support DCS as a useful tool for the diagnosis of cerebral diseases in adults, children, and neonates.

3.1.2. Therapeutic monitoring of cardio-cerebral diseases. DCS has been used to evaluate the effects of surgical interventions on CBF in adults and infants. Those surgeries included carotid endarterectomy in adults (Shang et al 2011b), thrombolysis in adults (Zirak et al 2014), and cardiac surgery in infants (Buckley et al 2013).

Carotid endarterectomy (CEA) is a surgical intervention to restore the blood supply to brain through removal of the blockage in carotid artery (Shang et al 2011b). During CEA, some of major vessels are temporarily clamped, causing a shutdown of blood supply to local cerebral tissues. Thus, intraoperative monitoring of CBF variation is particularly important as
it permits acute assessment of cerebral hemodynamic level during surgery and post-surgical hemodynamic improvement in the brain. Electroencephalography (EEG) is an often-used technology for cerebral monitoring during CEA, which offers indirect assessment of cerebral ischemia through analysis of brain waves. In a comparison study of EEG and DCS measurements for evaluating cerebral hemodynamic variations during CEA, EEG electrodes were placed all over the scalps of eleven patients undergoing CEA, and two optical probes were taped on both sides of forehead for simultaneous measurements of CBF and cerebral oxygenation. The internal carotid artery (ICA) clamps during CEA resulted in significant CBF decreases (−24.7 ± 7.3%, assigning a baseline of 100%) at the surgical sides (figure 6(a)). On the other hand, post-CEA CBF values were significantly higher (+43.2 ± 16.9%, assigning a baseline of 100%) than pre-CEA CBF values. Flow compensation via circle of Willis was also observed at the nonsurgical side (figure 6(b)). CBF responses to ICA clamping were found to be significantly faster, larger, and more sensitive than EEG responses (figure 7). Simultaneous monitoring of CBF and EEG provided a comprehensive evaluation of cerebral physiological status and showed potential for the adoption of acute interventions (e.g. shunting, medications) during CEA to reduce the risks of severe cerebral ischemia and cerebral hyperperfusion syndrome.

DCS was also applied to a patient with acute ischemic stroke, who received thrombolytic therapy to restore CBF (Zirak et al 2014). CBF was monitored by DCS throughout the 60 min thrombolytic therapy. DCS data showed an acute improvement in CBF after thrombolytic therapy, which agreed with the improvement in stroke scale score. This study suggested the potential of continuous DCS monitoring for therapeutic evaluation of acute stroke.

DCS measurements of CBF during interventions were also reported in infants. For example, CBF, cerebral oxygenation, and cerebral oxygen metabolism were continuously monitored during the period of postoperative neonatal cardiac surgery using a hybrid optical instrument (Buckley et al 2013). Due to the complicated communications between the cerebral and cardiac vessels, the surgeries on hearts were found to significantly affect cerebral oxygen extraction fraction, but not CBF and cerebral metabolic rate of oxygen consumption.

In summary, many intervention strategies for cardio-cerebral diseases are to restore tissue blood flow. Studies presented in this subsection show high sensitivity of DCS for continuous monitoring of CBF variations during interventions, which holds the potential for dynamic assessment and optimization of cardio-cerebral interventions to maintain CBF in a normal level.

3.2. Skeletal muscle

3.2.1. Diagnosis of muscular diseases. DCS has been adopted to evaluate the vascular diseases affecting skeletal muscle perfusion such as fibromyalgia and peripheral arterial disease (Shang et al 2012, Mesquita et al 2013). Evaluation of muscular diseases was often performed in a dynamic manner because those diseases restrict patients from performing leg or arm exercises. Blood flow responses to exercise reflect how skeletal muscles properly perform physiological functions.

In a study of fibromyalgia (FM) (Shang et al 2012), women with FM were instructed to perform knee extension exercises with steadily increasing intensity. Calf muscle hemodynamics was continuously monitored by a hybrid instrument during exercise using a probe illustrated in figure 3(c). Results showed that subjects with FM had significantly lower oxygen extraction rate during exercise than healthy controls, and the time of oxygenation recovery
Figure 6. Typical relative changes in cerebral blood flow (rCBF) (a) at the surgical side (ipsilateral) and (b) at the nonsurgical side (contralateral). This figure is reproduced from subfigures of figure 2 in Shang et al (2011b).

Figure 7. Comparison of DCS and EEG measurement results in a typical patient during carotid endarterectomy (CEA) when the internal carotid artery (ICA) was temporarily clamped. The resulted ischemic status by the ICA clamping was characterized by the slope ($S$), $D$-index, and time-to-minimum for both CBF (top panel) and EEG (bottom panel) at the surgical side. Here the slope ($S$) is the decreasing rate of variable $D(t)$ during the first 30 s clamping period, and $D(t)$ represents the percentage change of variable (CBF or EEG spectral power) at time $t$, when compared to pre-clamping baseline. The minimum of $D(t)$ during the entire period of clamping is defined as $D$-index, representing the most severe cerebral hypoperfusion during ICA clamping. The period from the beginning of clamping to the time of $D(t)$ attaining its minimum ($D$-index) is defined as time-to-minimum. The large negative CBF slope ($S = -1.25$) during the first 30 s clamping period indicates the rapid CBF decrease due to ICA clamping (a). The time duration of CBF decrease and maximal CBF decrease during the entire clamping period were characterized by time-to-minimum (80 s) and $D$-index ($-66.2\%$), respectively (b). By contrast, the EEG power changes were small and slow ($S = 0.11$) (c), and reached its minimum ($D$-index = $-42.8\%$) in a long period of time (time-to-minimum = 1016 s) (d). This figure is reproduced from figure 4 in Shang et al (2011b).
were significantly longer. These results suggested an alteration of muscle oxygen utilization in the FM population.

In another study investigating the influence of peripheral arterial disease (PAD) on skeletal muscle hemodynamics (Mesquita et al. 2013), calf blood flow values were found to occur at more depressed levels in PAD population after treadmill and pedal exercises, compared to those in age-matched healthy people. These results indicated adverse impact of PAD on blood flow responses to exercise.

Limitations existed when using DCS techniques to continuously monitor muscle hemodynamic changes during exercise, such as the nature of relative measurement (rBF) and the motion artifact induced by the exercise. To overcome these limitations, our group recently created a calibration protocol for absolute flow measurements and a gating algorithm to minimize motion artifacts during exercise (Gurley et al. 2012, Henry et al. 2015). Briefly, a hybrid DCS/NIRS instrument along with a pre-exercise arterial occlusion protocol was utilized to quantify the absolute baseline blood flow value before exercise. The absolute baseline flow value was then used to calibrate the measured rBF during exercise in order to obtain absolute flow measurements over the entire exercising period. Motion artifacts were minimized using a novel dynamometer-based gating algorithm embedded in the DCS control software. Essentially, this software determined muscle contraction status based on signals from the dynamometer and recorded data only when muscle fiber motion was minimal.

The innovative calibration and gating algorithms have been recently applied on patients with FM and compared with age-matched healthy controls. Blood flow responses in forearm muscles to handgrip exercise were continuously monitored and patients with FM exhibited less capability to perform handgrip exercise than healthy controls, evidenced by the weaker blood flow responses during exercise (figure 8).

Overall, deficiency of skeletal muscle function may result from mitochondrial dysfunction (Cordero et al. 2010), lower capillary density (Lindh et al. 1995, Morf et al. 2005), reduced capillary permeability (Grassi et al. 1994) and impaired vasodilatory capacity (Kasikcioglu et al. 2006, McIver et al. 2006), all of which are difficult to measure noninvasively. Hybrid DCS/NIRS devices enable noninvasive dynamic quantification of blood flow, blood oxygenation, and oxidative metabolism during exercise, providing unique and comprehensive diagnostic information for skeletal muscle diseases.

3.2.2. Therapeutic monitoring of muscular diseases. A few studies have been reported using DCS to investigate the impacts of surgical interventions on skeletal muscle diseases (Yu et al. 2011, Huang et al. 2015c). For muscular revascularization, ultrasound Doppler is routinely used in surgical rooms to test post-surgical reperfusion in large vessels. However, ultrasound Doppler cannot directly assess the restoration of tissue microcirculation, which is generally the major goal of revascularization.

Using a portable DCS flow-oximeter and the probe illustrated in figure 3(c) (Shang et al. 2009), we continuously monitored calf muscle blood flow variations on twelve human limbs undergoing artery revascularization (Yu et al. 2011). The high sensitivity of DCS in detecting blood flow changes was confirmed through clamping or ballooning on/off the femoral or aorta arteries during surgeries. Furthermore, immediate hyperemia following the release of occlusions and post-surgery flow improvements in calf muscles were observed, indicating the potential of the DCS for objective assessment of revascularization effects.

Another representative application of DCS is the assessment of blood flow in free transfer muscle flaps following salvage surgeries in patients with head and neck cancer. Conventional approaches to evaluate the success of tissue flaps rely on visual examination along with blood flow measurements in large vessels by ultrasound Doppler. DCS offers a tool to directly assess
tissue blood flow in peripheral muscle flaps, which is crucial to evaluate the success of surgeries. For intraoperative monitoring of reconstructive flaps, we designed a lens system which focused the sources and detectors on the tissue surface, permitting noncontact measurements of flap blood flow (see figure 3(f)) (Huang et al. 2015c). The noncontact DCS probe was applied to eight free muscle flaps at multiple time points of blood flow measurements during and post the surgical operations. Figure 9 shows comparison results obtained from seven successful flaps and one unsuccessful flap. Postoperative blood flow values in the successful flaps were significantly higher than the intraoperative baseline values, indicating a gradual recovery of flap vascularity after the tissue transfer. By contrast, postoperative blood flow recovered much less in the unsuccessful flap. Measurement of blood flow recovery after flap anastomosis holds the potential to act early to salvage ischemic flaps.

3.3. Tumor

3.3.1. Diagnosis of tumors. The first translational case of DCS for clinical cancer diagnosis was reported on human breast tumors (Durduran et al. 2005). Through scanning over the breast tumors \( n = 5 \) using a contact optical probe illustrated in figure 3(d), higher blood flow contrasts were found in malignant (230% by averaging over three subjects) and benign (153% by averaging over two subjects) tumors, respectively, as compared to the surrounding normal tissues (assigning 100%). Similar measurement configuration was thereafter applied to a larger population with breast tumors \( n = 32 \) (Choe et al. 2014), confirming the high blood flow contrasts in breast tumors (225–227% in mean value and 190–270% in 95% confidence intervals).

Moreover, a recent pilot study investigated the correlations between tumor hemodynamic parameters (i.e. blood flow, \([\text{HbO}_2]\), \([\text{Hb}]\), \( \text{StO}_2 \), THC) and tumor histopathological biomarkers. Increased blood supply to breast tumors was observed, which agreed with the high
expression level of Ki67 nuclei in the confirmed breast tumors (Chung et al. 2015). This study suggested that the macroscopic measurements of tissue hemodynamics could reveal pathological properties of breast cancer in microscopic level.

A significant problem with contact DCS measurements described above is the deformation of soft breast tissue, which may distort blood flow distribution in the soft breast. To solve this problem, noncontact DCS/DCT (ncDCS/ncDCT) systems with unique fiber-optic probes were recently developed enabling fully noncontact measurement/imaging of blood distributions in deep tissue volumes with complex boundaries (Lin et al. 2012, Li et al. 2013, Lin et al. 2014, He et al. 2015, Huang et al. 2015b, 2015c). The noncontact probe was attached to a motorized stage that scanned linearly or rotationally over a ROI (figure 4). Figure 10 shows in vivo imaging results from two breast carcinomas. Higher blood flow contrasts (5.9- and 10.9-fold) in the tumor regions compared to the surrounding tissues were observed. The reconstructed locations of the two tumors matched ultrasound imaging results when the tumor was within the sensitivity region of diffuse light. The ncDCT system showed the promise to image blood flow distributions in soft and vulnerable tissues without distorting tissue hemodynamics.

The autonomic growth and spread of tumors are dependent on increased angiogenesis arising from the increased metabolic demand. Since functional alternations in tumors often appear earlier than detectable morphological changes, functional imaging of tumor blood flow by DCT is a new strategy for early cancer diagnosis and localization.

3.3.2. Therapeutic monitoring of tumor treatments. It has been found that the patients with hypoxic tumors show incomplete clinical responses when receiving chemo-radiation therapy that requires tissue oxygen for treatment efficacy (Busch et al. 2000, Carlson 2006). Many tumors are hypoxic because of abnormal vasculature, malignancy-related anemia, and/or high oxygen consumption by tumor cells. Studies have shown that pretreatment tumor hypoxia is associated with significantly poor responses to the therapy when compared to oxygenated
However, some well-oxygenated tumors failed to respond while some hypoxic tumors responded well, possibly due to the dynamic changes during treatment in tumor oxygen status induced by radiation. Therefore, repeated monitoring of individual tumor hemodynamic status during therapy may provide predictive information for treatment outcomes.

To date, DCS has been utilized to monitor the tumor hemodynamic responses to chemoradiation therapy in breast tumors (Zhou et al 2007) and head/neck tumors (Sunar et al 2006, Dong et al 2012b, Dong et al 2016). In a case study of breast cancer using a hybrid DCS/NIRS device, significant changes in tumor blood flow and blood oxygenation were observed in the first week of chemo-radiation therapy (Zhou et al 2007).

In another pilot study of head/neck tumors using a hybrid DCS/NIRS instrument, tumor hemodynamic responses in a small group of patients (n = 8) were continually measured once a week over the period of chemo-radiation therapy (Sunar et al 2006). Tumors exhibited significant dynamic flow and oxygenation changes during the first four weeks of the treatment.
This study, however, was limited by the small number of patients examined and only one patient out of 8 showed a partial response to the treatment.

Very recently, our group employed a hybrid DCS/NIRS instrument to continually monitor tumor hemodynamic responses to chemo-radiation therapy for early prediction of treatment outcomes in a relative large patient population with head/neck cancers (Dong et al. 2016). Forty-seven patients were measured once per week over 7 weeks of treatment period to evaluate the hemodynamic status of clinically involved cervical lymph nodes. Patients were classified into two groups: complete response (CR) \((n = 29)\) and incomplete response (IR) \((n = 18)\). Interestingly, tumor hemodynamic responses were found to be associated with clinical outcomes (CR/IR), wherein the associations differed depending on human papillomavirus (HPV-16) status. In HPV-16 positive patients, significantly lower levels in tumor \([\text{HbO}_2]\) at weeks 1 to 3, THC at week 3, and StO\(_2\) at week 3 were found in the IR group. In HPV-16 negative patients, significantly higher levels in tumor BFI and \(\mu_s'\) at week 3 were observed in the IR group. These hemodynamic parameters exhibited significantly high accuracies for early prediction of clinical outcomes, within the first three weeks of therapy, with the areas under the receiver operating characteristic curves (AUCs) ranging from 0.83 to 0.96 (figure 11).

Overall, tumor hemodynamic parameters exhibited significantly high accuracies for early prediction of clinical outcomes. Such predictions, based on frequent optical measurements, may ultimately be used to optimize individual therapeutic outcomes at an early time of therapy. For example, treatment outcomes may be improved by dynamically promoting oxygenation levels (e.g. hyperbaric oxygen therapy) in HPV-16 positive tumors or inhibiting angiogenesis (e.g. anti-VEGF antibody) in HPV-16 negative tumors.

4. Summary and future perspectives

In contrast to large imaging modalities such as CT, MRI, and PET, optical instruments such as NIRS/DOS/DOT and DCS/DCT are portable, fast, inexpensive, and suitable for continuous measurements at the bedside of clinical settings. NIRS/DOS/DOT techniques have been extensively used to measure tissue oxygenation in the clinic. Compared to NIRS/DOS/DOT, DCS/DCT is a relatively new technique that enables direct measurement of tissue blood flow. DCS/DCT or hybrid DCS/NIRS is being increasingly employed worldwide in a large variety of clinical contexts for the diagnosis and therapeutic monitoring of various diseases affecting tissue hemodynamics and metabolism. Overall, these pilot clinical studies in relatively small populations have shown the technique’s versatility and demonstrated that the method provides new and complementary information about patient pathophysiology in a noninvasive fashion. It should be noticed that DCS/DCT has only been applied to a small population of patients with short measurement time frames (minutes to several weeks). Longitudinal studies in large populations are needed to elucidate potential unresolved technical problems and translate DCS/DCT into the clinic as a routine diagnostic and monitoring tool.

There has been a concern on the physical modeling of blood flow (i.e. the motion of red blood cells) in the microvasculature. It was found that diffusive motion (see section 2.1) fits the experimental autocorrelation curves rather well over a broad range of tissue types (Durduran 2004, Zhou 2007). Intuitively, however, random ballistic flow would be considered as a better model to fit the DCS/DCT data. Modified mixture models were proposed to include both ballistic flow and diffusive motion (Carp et al. 2011, Boas et al. 2016). Experimental data supported the proposed models for capturing the transition from early ballistic to subsequent diffusive motion. Computer simulations on the tissue with varied vessel diameters and spacing showed that the diffusive motion dominates the correlation decay in typical DCS
measurements, and the blood flow index is modulated proportionally by the concentration of hemoglobin and the average diameter of blood vessels. Nevertheless, more clinical investigations are needed for accurate extracting of blood flow information in deep tissues.

Some technical issues exist when applying NIR diffuse optical technologies to deep tissues with heterogeneous properties. Since NIRS and DCS techniques rely on the transport of NIR light through top layer tissues (e.g. skin, skull), both methods must account for partial volume contributions from the top layer-structure to the deep tissue signals (e.g. brain, muscle, and tumor). In addition, measurement signal-to-noise ratio (SNR) and penetration depth are two interrelated and important parameters that affect the utility of both DCS and NIRS. Furthermore, most research with DCS reports only relative changes of blood flow index with respect to some baseline condition.

The ‘partial volume effect’ substantially affects the accuracy of DCS measurements, as discussed in literature (Strangman et al 2003, Yu 2012a, Durduran and Yodh 2014). Slab-layered models were proposed to reduce the partial volume effect (Li et al 2005, Jaillon et al 2006, Verdecchia et al 2016). A recently developed method, ‘Modified Beer–Lambert law for blood flow’, has been proved to be effective in pressure modulation experiments to reduce the skin-effect on cerebral blood flow measurements (Baker et al 2014, 2015). However, those methods ignored the influence of irregular tissue geometries. Recently, we created a new algorithm integrating a linear model of autocorrelation function with the Monte Carlo simulation of photon migrations in heterogeneous tissues with arbitrary geometries for simultaneous extraction of blood flow indices in multiple layered tissues (Shang and Yu 2014).

Compared to NIRS/DOS/DOT, DCS/DCT measurements have relatively lower SNRs when probing deep tissue blood flow with large S-D separations (e.g. >2.5 mm). This is due to the utilization of single-mode detector fibers with a small core diameter of 5 µm in DCS/DCT measurements to ensure the detection of autocorrelation functions of light intensity. Efforts

Figure 11. Receiver operating characteristic curves (ROC) and the associated areas under the curve (AUC) for discriminating tumors with incomplete response (IR) or complete response (CR). (a) and (b) [HbO2] at week 1 and week 3 in HPV-16 positive patients, (c) THC at week 3 in HPV-16 positive patients, (d) StO2 at week 3 in HPV-16 positive patients, (e) BFI in HPV-16 negative patients at week 3, and (f) µ′ in HPV-16 negative patients at week 3. This figure is reproduced from figure 5 in Dong et al (2016).
have been made to improve SNR through the spatial average of multiple autocorrelation functions detected by a detector fiber bundle (Dietsche et al. 2007) or the temporal average of DCS signals obtained by a fast software correlator (Wang et al. 2016).

A potential remedy for the absolute blood flow measurement problem is to calibrate DCS/DCT against a gold standard. As mentioned early, comparison studies in small populations have been done in skeletal muscles, tumors, and brains against other established methods including power spectral Doppler ultrasound (Yu et al. 2005b), Doppler ultrasound (Buckley et al. 2009, Roche-Labarbe et al. 2010), laser Doppler (Durduran 2004, Shang et al. 2011a), Xenon-CT (Kim et al. 2010), fluorescent microsphere flow measurement (Zhou et al. 2009), and ASL-MRI (Yu et al. 2007). Results from these studies show the promise to obtain absolute flow measurements although further validation works need to be done with different types of tissues in large populations.

DCT/ncDCT enables 3D imaging of blood flow distributions in deep tissues. While effective, ncDCS/ncDCT employs a limited number of expensive APDs for blood flow detection, leading to low spatiotemporal resolution and high instrument cost (Lin et al. 2014, He et al. 2015, Huang et al. 2015b). With current ncDCT, the ROI must be mechanically scanned for a complete tissue coverage, which can take up to 40 min and may result in motion artifacts. To overcome these limitations, we recently developed and tested a non-scanning, noncontact, fast, portable, cost-effective device, namely speckle contrast diffuse correlation tomography (scDCT), for 3D imaging flow distributions (Huang et al. 2015a, 2016). The scDCT used a charge-coupled-device (CCD) as a 2D detector array to cover a ROI, thus eliminating the mechanical scanning and consequent problems. Thousands of detectors provided by the CCD significantly improved spatiotemporal resolution and reduced instrument cost/size. The scDCT prototype has been tested using computer simulations and tissue phantoms with anomaly flow contrast design. We are currently translating this novel optical technique to the clinic.

It is well known that many diseases are associated with tissue hypoxia, which is influenced by oxygen supply (i.e. blood flow) and tissue oxygen consumption. Simultaneous measurements of tissue blood flow and blood oxygenation using combined DCS and NIRS instruments enable the evaluation of tissue metabolic rate of oxygen consumption (Durduran et al. 2004, Roche-Labarbe et al. 2010, Durduran et al. 2010b, Shang et al. 2012, Buckley et al. 2013, Dehaes et al. 2014, Henry et al. 2015, Gurley et al. 2012, Chung et al. 2015, Lin et al. 2016). This metabolic parameter is potentially a more direct indicator of tissue metabolic activities, which integrates many factors and provides further insight about tissue pathophysiology. It is expected that with further technology development and more clinical applications, DCS/DCT and hybrid DCS/NIRS technologies will be eventually utilized as routine diagnostic and intervention monitoring tools for clinical investigations of various diseases.
